## Question 1

a The savings problem of a young individual is

$$\begin{aligned} \max_{c_{1t}, c_{2t+1}} \quad & \ln c_{1t} + \frac{1}{1+\rho} \ln c_{2t+1}, \\ & c_{1t} + s_t = w_t(1-\tau), \\ & c_{2t+1} = s_t(1+r_{t+1}) + (1+n)\tau w_{t+1}. \end{aligned}$$

Solving this problem and combining the FOCs yields the Euler equation

$$c_{2t+1} = \frac{1+r_{t+1}}{1+\rho} c_{1t}.$$

Replace  $c_{1t}$  and  $c_{2t+1}$  from the budget constraints to obtain the desired equation describing individual savings behavior:

$$s_t = \frac{1}{2+\rho} w_t(1-\tau) - \tau \frac{1+\rho}{2+\rho} \frac{1+n}{1+r_{t+1}} w_{t+1}.$$

b To derive the capital accumulation equation we use individual savings and replace  $k_{t+1} = \frac{s_t}{1+n}$ , and use the equilibrium expressions for wages and rental rates to obtain

$$k_{t+1} = \frac{1}{(2+\rho)(1+n)} (1-\tau)(1-\alpha) A k_t^\alpha - \frac{1+\rho}{2+\rho} \tau \frac{1-\alpha}{\alpha} k_{t+1}.$$

Thus, we rearrange this expression to obtain

$$k_{t+1} = \frac{1}{1 + \frac{1+\rho}{2+\rho} \frac{(1-\alpha)}{\alpha} \tau} \left[ \frac{(1-\alpha)(1-\tau)}{(1+n)(2+\rho)} A k_t^\alpha \right].$$

Imposing the steady state we get

$$\bar{k} = \left[ \frac{1}{1 + \frac{1+\rho}{2+\rho} \frac{(1-\alpha)}{\alpha} \tau} \frac{(1-\alpha)(1-\tau)}{(1+n)(2+\rho)} A \right]^{\frac{1}{1-\alpha}}.$$

c The savings problem of a young individual now reads as

$$\begin{aligned} \max_{c_{1t}, c_{2t+1}} \quad & \ln c_{1t} + \frac{1}{1+\rho} \ln c_{2t+1}, \\ & c_{1t} + s_t = w_t(1-\tau), \\ & c_{2t+1} = (s_t + w_t\tau)(1+r_{t+1}). \end{aligned}$$

Solving this problem and combining FOCs yields the Euler equation

$$c_{2t+1} = \frac{1+r_{t+1}}{1+\rho} c_{1t}.$$

Replace  $c_{1t}$  and  $c_{2t+1}$  from the budget constraints to obtain the desired equation describing individual savings behavior:

$$\begin{aligned} (s_t + d_t)(1+r_{t+1}) &= \frac{1+r_{t+1}}{1+\rho} [w_t - s_t - d_t] \\ s_t + d_t &= \frac{1}{2+\rho} w_t \end{aligned}$$

Thus:

$$k_{t+1} = \frac{s_t + d_t}{1+n} = \frac{1}{(1+n)(2+\rho)} w_t,$$

and, as  $w_t = (1-\alpha)Ak_t^\alpha$ :

$$\bar{k}' = \left[ \frac{(1-\alpha)A}{(1+n)(2+\rho)} \right]^{\frac{1}{1-\alpha}}.$$

d As the policy-switch takes place before saving decisions are formulated, the old generation in  $T$  finds itself with no pension. Thus, old in  $T$  are worse-off. The government could compensate them by issuing public debt, reimbursable by taxes to be paid by the future young generations, so that the current generation of workers would not be affected.

## Question 2

a Given the linear rule  $\pi_t = \psi + \psi_\theta \theta_t$ , as well as the fact that  $\theta_t$  is observed by both the public and the policy maker before expectations are formed, output is determined as follows:

$$x_t = \theta_t + \pi_t - \pi_t^e = \theta_t + \psi + \psi_\theta \theta_t - (\psi + \psi_\theta \theta_t) = \theta_t$$

Thus, the expected loss reads as:

$$\begin{aligned}
E[L(\pi_t, x_t)] &= \frac{1}{2} E \left[ \left( \underbrace{\psi + \psi_\theta \theta_t}_{=\pi_t} \right)^2 + \lambda \left( \underbrace{\theta_t}_{=x_t} - \bar{x} \right)^2 \right] \\
&= \frac{1}{2} E [\psi^2 + 2\psi\psi_\theta\theta_t + \psi_\theta^2\theta_t^2 + \lambda(\theta_t^2 - 2\bar{x}\theta_t + \bar{x}^2)] \\
&= \frac{1}{2} \left[ \psi^2 + 2\psi\psi_\theta \underbrace{E[\theta_t]}_{=0} + \psi_\theta^2 \underbrace{E[\theta_t^2]}_{=\sigma_\theta^2} + \lambda \left( \underbrace{E[\theta_t^2]}_{=\sigma_\theta^2} - 2\bar{x} \underbrace{E[\theta_t]}_{=0} + \bar{x}^2 \right) \right]
\end{aligned}$$

Taking the first order conditions of  $E[L(\pi_t, x_t)]$  with respect to  $\psi$  and  $\psi_\theta$  we obtain:

$$\begin{aligned}
\frac{\partial E[L(\pi_t, x_t)]}{\partial \psi} &= 0 : \psi = 0 \\
\frac{\partial E[L(\pi_t, x_t)]}{\partial \psi_\theta} &= 0 : \psi_\theta \sigma_\theta^2 = 0
\end{aligned}$$

Thus, the expected loss is minimized by setting  $\psi = \psi_\theta = 0$ , which implies  $\pi_t^C = 0$  and  $x_t^C = \theta_t$ .

- b** When the central bank conducts a discretionary policy, the inflation rate is chosen after expectations are formed. Hence, the goal of the central bank is to minimize the loss function, i.e. the monetary policy should be ex post optimal, given  $\pi_t^e$ . Under this assumption, the problem reads as

$$\min_{\pi_t} \frac{1}{2} [\pi_t^2 + \lambda(\theta_t + \pi_t - \pi_t^e - \bar{x})^2]$$

The first order condition for this problem reads as:

$$\frac{\partial L(\pi_t, x_t)}{\partial \pi_t} = 0 : \pi_t + \lambda(\theta_t + \pi_t - \pi_t^e - \bar{x}) = 0 \Leftrightarrow \pi_t^D = \frac{\lambda}{1 + \lambda} (\pi_t^e - \theta_t + \bar{x})$$

Thus, the expected rate of inflation is found by taking expectations:

$$E[\pi_t^D | \theta_t] = \frac{\lambda}{1 + \lambda} E_t[\pi_t^e - \theta_t + \bar{x}] = \frac{\lambda}{1 + \lambda} (E_t[\pi_t^D | \theta_t] - \theta_t + \bar{x})$$

which implies  $E[\pi_t^D | \theta_t] = -\lambda(\theta_t - \bar{x})$ . Therefore:

$$\begin{aligned}
\pi_t^D &= \frac{\lambda}{1 + \lambda} \left( \underbrace{-\lambda(\theta_t - \bar{x})}_{=\pi_t^e} - \theta_t + \bar{x} \right) = -\lambda(\theta_t - \bar{x}) \\
x_t^D &= \theta_t
\end{aligned}$$

The excessively high equilibrium inflation associated with the inflation bias problem results from the combination of a lack of commitment and central bank's temptation to temporarily boost the economy beyond its potential level. The latter incentive is embodied by the condition  $\bar{x} > \theta$ . This makes it clear why raising  $\bar{x}$  increases the temptation of the central bank to generate excess inflation in the vain attempt to stimulate real activity.

- c** Once again, when the central bank conducts a discretionary policy, the inflation rate is chosen after expectations are formed. Hence, the goal of the central bank is to minimize the loss function, i.e. the monetary policy should be ex post optimal, now given  $\pi_t^e$  and  $\theta_t$ , as the latter is not observed. Under this assumption, the problem reads as

$$\min_{\pi_t} \frac{1}{2} [\pi_t^2 + \lambda (\theta_t + \pi_t - \pi_t^e - \bar{x})^2]$$

The first order condition for this problem reads as:

$$\frac{\partial L(\pi_t, x_t)}{\partial \pi_t} = 0 : \pi_t + \lambda (\theta_t + \pi_t - \pi_t^e - \bar{x}) = 0 \Leftrightarrow \pi_t^D = \frac{\lambda}{1 + \lambda} (\pi_t^e - \theta_t + \bar{x})$$

Now, the expected rate of inflation is found by taking unconditional expectations (as  $\theta_t$  is not observed before expectations are formed):

$$E [\pi_t^D] = \frac{\lambda}{1 + \lambda} E [\pi_t^e - \theta_t + \bar{x}] = \frac{\lambda}{1 + \lambda} (E [\pi_t^D] + \bar{x})$$

which implies  $E [\pi_t^D] = \lambda \bar{x}$ . Therefore:

$$\begin{aligned} \pi_t^{D*} &= \frac{\lambda}{1 + \lambda} \left( \underbrace{\lambda \bar{x}}_{=\pi_t^e} - \theta_t + \bar{x} \right) = \frac{\lambda}{1 + \lambda} [\bar{x} (1 + \lambda) - \theta_t] \\ x_t^{D*} &= \theta_t + \frac{\lambda}{1 + \lambda} [\bar{x} (1 + \lambda) - \theta_t] - \lambda \bar{x} = \frac{1}{1 + \lambda} \theta_t \end{aligned}$$

As we set  $\lambda = 0$ , the policy maker does not face a real activity stabilization objective, so that there is no temptation to inflate the economy to raise output above the target. Thus, no matter the information structure, output will always be equal to  $\theta_t$ , and thus to its solution under commitment. The same holds true for the rate of inflation.

- d** No, as such a trade-off emerges only in the presence of supply-side shocks, which are not contemplated by this model.
